

## PHYSICS C2801 FALL 2017 PROBLEM SET 1

LAURA HAVENER  
EDITED BY BENJAMIN CHURCH

### Problem 1. Approximations

a.) A Taylor Expansion is a way of representing a function as an infinite sum of terms and is a way to represent functions in simpler forms that are easier to use mathematically. This problem asks you to take expansion of  $\tan(\theta)$ . The general form of a Taylor Expansion around a particular value  $a$  is:

$$\begin{aligned} f(x) &= f(a) + \frac{f'(a)}{1!}(x-a) + \frac{f''(a)}{2!}(x-a)^2 + \frac{f'''(a)}{3!}(x-a)^3 + \dots = \sum_{n=0}^{\infty} \frac{f^{(n)}(a)}{n!}(x-a)^n \\ n! &= n(n-1)(n-2)(n-3)(n-4)\dots \end{aligned}$$

In the case the value to expand around is  $\theta = 0$ , which means in the equation above  $a = 0$ . Start by taking the derivatives of  $\tan(\theta)$  with respect to  $\theta$ .  $\tan(0) = 0$  so the first 3 nonzero terms are the ones that contain the first 3 derivatives.

$$\begin{aligned} \frac{d \tan(\theta)}{d\theta} &= \sec^2(\theta) \\ \frac{d^2 \tan(\theta)}{d\theta^2} &= 2 \sec(\theta) \frac{d \sec(\theta)}{d\theta} = 2 \sec(\theta) \sec(\theta) \tan(\theta) = 2 \sec^2(\theta) \tan(\theta) \\ \frac{d^3 \tan(\theta)}{d\theta^3} &= 2(2 \sec^2(\theta) \tan(\theta) \tan(\theta) + \sec^2(\theta) \sec^2(\theta)) = 2 \sec^2(\theta)(2 \tan^2(\theta) + \sec^2(\theta)) \end{aligned}$$

Now put this into the expansion:

$$\begin{aligned} \tan(\theta) &\approx \tan(0) + \frac{\sec^2(0)}{1!}(\theta-0) + \frac{2 \sec^2(0) \tan(0)}{2!}(\theta-0)^2 + \frac{2 \sec^2(0)(2 \tan^2(0) + \sec^2(0))}{3!}(\theta-0)^3 \\ \tan(\theta) &\approx 0 + \theta + 0 + 2 \frac{0+1}{3*2*1} \theta^3 = \theta + (2/6)\theta^3 \\ \tan(\theta) &\approx \theta + \frac{\theta^3}{3} \end{aligned}$$

To see a quicker way of doing this look at the end of part b of this problem. Then the problem states that  $\theta \ll 1$  so that  $\tan(\theta)$  can be approximated by the first term in the expansion. This is a very important concept to remember because this is often used to approximate solutions to physics problems and you will do this often in this course and in the future. Remember that functions can be approximated through the Taylor Expansion and then if the arguments are small they can be approximated further by dropping terms. This approximation is called the small-angle approximation and can be used on other trigonometric functions also. This then makes solving problems a lot easier.

$$\tan(\theta) \approx \theta$$

The problem goes on to discuss the relative error of the expansion. This tells you how accurate the

approximation you made actually is for different values of  $\theta$ . This relative error is found by taking the ratio of the second non-zero term in the expansion to the first:

$$err_{rel} \approx \frac{\theta^3/3}{\theta} = \theta^2/3$$

Then you can use different values of  $\theta$  to figure out how accurate the approximation is. The problem asks you to work backward though and find the values of  $\theta$  that give you certain errors. Keep in mind that when you do the Taylor Expansion in  $\theta$ , the  $\theta$  is in radians not degrees. Thus in order to complete the problem the angle has to be converted to degrees to get both like the problem asks for. The different errors given are 10, 1, and 25 percent.

$$\begin{aligned} err_{rel} &\approx \theta^2/3 \\ \theta &\approx 3\sqrt{err_{rel}} \\ \theta &\approx 3\sqrt{0.1} = 0.94868 \text{ rad} \\ \theta &\approx (0.94868)\frac{180}{\pi} = 54.356^\circ \\ \theta &\approx 3\sqrt{0.01} = 0.3 \text{ rad} \\ \theta &\approx (0.3)\frac{180}{\pi} = 17.189^\circ \\ \theta &\approx 3\sqrt{0.25} = 1.5 \text{ rad} \\ \theta &\approx (1.5)\frac{180}{\pi} = 85.944^\circ \end{aligned}$$

b.) This part is about the binomial approximation, which is another very important and useful approximation for solving physics problems. The formula is as follows, where  $\delta \ll 1$  and  $a$  is any power (positive or negative):

$$(1 + \delta)^a \approx 1 + a\delta$$

The problem asks for you to do this on the hypotenuse of a right triangle with sides  $d$  and  $L$ , where  $d \ll L$ . The equation for this is as follows:

$$h = \sqrt{L^2 + d^2}$$

The first step is to manipulate this equation to look like the general equation for the binomial expansion so the approximation can be directly applied. This means factoring out the  $L^2$  to get a 1 as the first term and turning the square root into a power:

$$h = (L^2(1 + \frac{d^2}{L^2}))^{1/2} = L(1 + \frac{d^2}{L^2})^{1/2}$$

Then apply the approximation where  $\delta = \frac{d^2}{L^2}$  and  $a = 1/2$  to get:

$$h \approx L(1 + (1/2)\frac{d^2}{L^2}) = L + \frac{d^2}{2L}$$

This technique could have helped simplify the work you had to do for part a. Instead of taking

derivatives of tangent multiple times, you could have done this:

$$\begin{aligned}\tan(\theta) &= \frac{\sin(\theta)}{\cos(\theta)} \\ \sin(\theta) &\approx \sin(0) + \cos(0)x - (1/2)\sin(0)x^2 - (1/6)\cos(0)x^3 = x - x^3/6 \\ \cos(\theta) &\approx \cos(0) - \sin(0)x - (1/2)\cos(0)x^2 + (1/6)\sin(0)x^3 = 1 - x^2/2 \\ \tan(\theta) &\approx \frac{x - x^3/6}{1 - x^2/2} = (x - x^3/6)(1 - x^2/2)^{-1} \text{ (use binomial expansion)} \\ \tan(\theta) &\approx (x - \frac{x^3}{6})(1 + \frac{x^2}{2}) = x + \frac{x^3}{2} - \frac{x^3}{6} - \frac{x^5}{12} \text{ (drop the last term because it is of higher order)} \\ \tan(\theta) &\approx x + x^3/3\end{aligned}$$

This is the same answer we got for part a, with a lot less work.

c.) Here the problem asks to show that the sum of two Taylor Expansions is the same as the Taylor Expansion of the sum. To do these kind of proofs, start by writing out both cases: the expansion of the individual functions and the expansion of the sum.

$$\begin{aligned}f(x) &= f(a) + \frac{f'(a)}{1!}(x-a) + \frac{f''(a)}{2!}(x-a)^2 + \frac{f'''(a)}{3!}(x-a)^3 + \dots \\ g(x) &= g(a) + \frac{g'(a)}{1!}(x-a) + \frac{g''(a)}{2!}(x-a)^2 + \frac{g'''(a)}{3!}(x-a)^3 + \dots \\ f(x) + g(x) &= f(a) + g(a) + \frac{(f+g)'(a)}{1!}(x-a) + \frac{(f+g)''(a)}{2!}(x-a)^2 + \frac{(f+g)'''(a)}{3!}(x-a)^3 + \dots\end{aligned}$$

Then start from either one and try to make it look like the other. Let's try to start with the functions separate and add them together. Then try to group terms to make it look like the case where the functions are added together first and then Taylor expanded.

$$\begin{aligned}f(x) + g(x) &= f(a) + \frac{f'(a)}{1!}(x-a) + \frac{f''(a)}{2!}(x-a)^2 + \frac{f'''(a)}{3!}(x-a)^3 \\ &\quad + g(a) + \frac{g'(a)}{1!}(x-a) + \frac{g''(a)}{2!}(x-a)^2 + \frac{g'''(a)}{3!}(x-a)^3 + \dots \text{ (group common terms)} \\ f(x) + g(x) &= f(a) + g(a) + \frac{f'(a)}{1!}(x-a) + \frac{g'(a)}{1!}(x-a) + \frac{f''(a)}{2!}(x-a)^2 \\ &\quad + \frac{g''(a)}{2!}(x-a)^2 + \frac{f'''(a)}{3!}(x-a)^3 + \frac{g'''(a)}{3!}(x-a)^3 + \dots \text{ (factor out common factors)} \\ f(x) + g(x) &= f(a) + g(a) + \frac{f'(a) + g'(a)}{1!}(x-a) + \frac{f''(a) + g''(a)}{2!}(x-a)^2 \\ &\quad + \frac{f'''(a) + g'''(a)}{3!}(x-a)^3 + \dots \text{ (combine common derivatives)} \\ f(x) + g(x) &= f(a) + g(a) + \frac{(f+g)'(a)}{1!}(x-a) + \frac{(f+g)''(a)}{2!}(x-a)^2 + \frac{(f+g)'''(a)}{3!}(x-a)^3 + \dots\end{aligned}$$

Thus we arrived at the form for the expansion of the two functions added together. This proves that the Taylor Expansions adds linearly, which is an important tool for approximating larger, more complicated equations.

d.) This part asks you to make an expansion of a more complicated function to first order in  $x/a$  where  $x \ll a$ . It states that it can be done using either the Taylor Expansion explicitly or by doing the binomial expansion. I will show you both, starting with the Taylor Expansion.

The first thing to notice is that this is 2 functions added together. Therefore, we can use the proof from part c of this problem set to do each function separately and then add them together at the end.

$$\begin{aligned}
 \frac{1}{a+x} &= a^{-1}(1+x/a)^{-1} \text{ (expand around } x/a = 0 \text{ since } x/a \ll 1) \\
 (x+a)^{-1} &\approx a^{-1}((1+0)^{-1} + (1/1!)(-1)(1+0)^{-2}(x/a-0)) = 1/a - (1/a)(x/a) \\
 &= 1/a - x/a^2 \\
 \frac{1}{a-x} &= a^{-1}(1-x/a)^{-1} \\
 (1-x/a)^{-1} &\approx a^{-1}((1-0)^{-1} + (1/1!)(-1)(-1)(1-0)^{-2}(x/a-0)) = 1/a + (1/a)(x/a) = 1/a + x/a^2 \\
 \frac{1}{a+x} - \frac{1}{a-x} &\approx 1/a - x/a^2 - 1/a - x/a^2 = -2x/a^2
 \end{aligned}$$

Then for the binomial approximation:

$$\begin{aligned}
 \frac{1}{a+x} &= a^{-1}(1+x/a)^{-1} \approx a^{-1}(1-x/a) = 1/a - x/a^2 \\
 \frac{1}{a-x} &= a^{-1}(1-x/a)^{-1} \approx a^{-1}(1+x/a) = 1/a + x/a^2 \\
 \frac{1}{x+a} - \frac{1}{x-a} &\approx 1/a - x/a^2 - 1/a - x/a^2 = -2x/a^2
 \end{aligned}$$

You get the same result either way but the binomial approximation was faster.

e.) This part asks you to take the binomial approximation of the same fractions, just added together and with an addition term. Use the results from part d for the binomial approximation and find the combination:

$$\frac{1}{a+x} + \frac{1}{a-x} - \frac{2}{a} \approx 1/a - x/a^2 + 1/a + x/a^2 - 2/a = 2/a - 2/a = 0$$

Getting 0 is a problem here because the approximation should give you a non-zero result. If you use the result for the Taylor Expansion you also get the same issue since the results were the same. Thus, the solution is to take the expansion out to the next term. There is a formula for the binomial expansion out to the second term but since that may be a rather unused formula I will be using the next term from the Taylor Expansion:

$$\begin{aligned}
 \frac{1}{a+x} &\approx a^{-1}((1+0)^{-1} + (1/1!)(-1)(1+0)^{-2}(x/a-0) \\
 &\quad + (1/2!)(-1)(-2)(1+0)^{-3}(x/a-0)^2) = 1/a - x/a^2 + x^2/a^3 \\
 \frac{1}{a-x} &\approx a^{-1}((1-0)^{-1} + (1/1!)(-1)(-1)(1-0)^{-2}(x/a-0) \\
 &\quad + (1/2!)(-1)(-1)(-2)(-1)(1-0)^{-3}(x/a-0)^2) = 1/a + x/a^2 + x^2/a^3 \\
 \frac{1}{x+a} + \frac{1}{a-x} - 2/a &\approx 1/a - x/a^2 + x^2/a^3 + 1/a + x/a^2 + x^2/a^3 - 2/a \\
 &= 2x^2/a^3
 \end{aligned}$$

Whenever you get 0 from an approximation, make sure to try the next terms in the expansion until a non-zero value is obtained.

## Problem 2. Oscillation Acceleration

This problem asks you to calculate the velocity and position for a time-dependent acceleration.

$$\begin{aligned}a(t) &= \left(\frac{eE_0}{m}\right) \cos(\omega t) \\a_0 &= \frac{eE_0}{m} \\a(t) &= a_0 \cos(\omega t)\end{aligned}$$

It is a good trick in physics problems that involve a lot of constants or just a lot of terms to make substitutions, like the book did for  $a_0$ , in order to simplify the math.

The next step is to integrate this and find the velocity by doing  $a = dv/dt$  and grouping the velocity and  $t$  terms on opposite sides of the equations like Brian did in lecture. Don't forget the dummy variables under the integral sign. The initial velocity is  $v_0$  and  $t_0 = 0$ :

$$\begin{aligned}a(t) &= \frac{dv}{dt} = a_0 \cos(\omega t) \\dv &= a_0 \cos(\omega t) dt \\\int_{v_0}^v dv' &= \int_0^t a_0 \cos(\omega t') dt' \\v'|_{v_0}^v &= a_0 \left(\frac{-1}{\omega} \sin(\omega t')\right) \Big|_0^t \\v - v_0 &= \frac{-a_0}{\omega} (\sin(\omega t) - \sin(0)) \\v(t) &= v_0 - \frac{a_0}{\omega} \sin(\omega t)\end{aligned}$$

Now integrate again to get the position where  $v(t) = dx/dt$  and the initial position  $x_0$ .

$$\begin{aligned}v(t) &= \frac{dx}{dt} = v_0 - \frac{a_0}{\omega} \sin(\omega t) \\dx &= (v_0 - \frac{a_0}{\omega} \sin(\omega t)) dt \\\int_{x_0}^x dx' &= \int_{t_0}^t (v_0 - \frac{a_0}{\omega} \sin(\omega t')) dt' \\x - x_0 &= (v_0 t' - \frac{a_0}{\omega^2} \cos(\omega t')) \Big|_0^t \\x - x_0 &= v_0 t - \frac{a_0}{\omega^2} \cos(\omega t) - (0 - \frac{a_0}{\omega^2} \cos(0)) \\x - x_0 &= v_0 t - \frac{a_0}{\omega^2} (\cos(\omega t) - 1) \\x(t) &= x_0 + v_0 t + \frac{a_0}{\omega^2} - \frac{a_0}{\omega^2} \cos(\omega t)\end{aligned}$$

The problem then states that  $v_0 = x_0 = 0$ .

$$\begin{aligned}v(t) &= -\frac{a_0}{\omega} \sin(\omega t) \\x(t) &= \frac{a_0}{\omega^2} (1 - \cos(\omega t))\end{aligned}$$

The problem then asks you to compare the result to those in the book, which are:

$$\begin{aligned}v(t) &= -\frac{a_0}{\omega}(\cos(\omega t) - 1) \\x(t) &= \frac{a_0}{\omega}t - \frac{a_0}{\omega^2}\sin(\omega t)\end{aligned}$$

Look at the limits in the velocity equation. Our equation can have velocities anywhere from  $v = -a_0/\omega$  to  $v = a_0/\omega$ . The book equation can have velocities anywhere from  $v = 0$  to  $v = 2a_0/\omega$ . Thus, the book equation for velocity is the kind of like the "square" of our equation because they have the same zeros but the book equation remains positive. Use the half-angle formula to prove this:

$$\begin{aligned}\sin^2(x) &= (1/2)(1 - \cos(2x)) \\ \sin^2(x/2) &= (1/2)(1 - \cos(x)) \\ v(t) &= \frac{a_0}{\omega}(1 - \cos(\omega t)) = \frac{2a_0}{\omega}\sin^2(\omega t/2)\end{aligned}$$

Thus, they are both oscillating velocities but one remains positive with a higher amplitude while the other oscillates between positive and negative values.

Do the same thing for the position equation. Our equation ranges from  $x = 0$  to  $x = \frac{2a_0}{\omega^2}$ . The book equation ranges from  $x = \frac{a_0}{\omega^2}(\pi/2\omega - 1)$  and  $x = \frac{a_0}{\omega^2}(\pi/2\omega + 1)$ . This isn't exactly the same because of the first term in the book equation, but you can rearrange our equation using the half-angle formula again.

$$x(t) = \frac{2a_0}{\omega^2}\sin^2(\omega t/2)$$

Thus for the position our equation is always positive and the book equation oscillates between positive and negative values with an offset.

**Problem 3.** Integrating  $\dot{x}$  when expressed as a function of  $x$  instead of  $t$ .

Brian mentions a transcendental equation in his description of this problem. A transcendental equation is an equation that can not be solved analytically but can be solved graphically, numerically, or by making approximations on the functions to be simpler functions that can be solved. An example is here, which can not be solved directly for  $x$ :

$$e^x = x^2 - \ln(x)$$

a.) A very important common equation to solve in physics:

$$\begin{aligned}\frac{dx}{dt} &= -\frac{x}{\tau} \\ x(t_0) &= x_0\end{aligned}$$

The first step is to collect all the terms that involve  $x$  on one side and the ones that involve  $t$  on the other so you can integrate both sides with respect to one variable as Brian did in his second equation in the problem:

$$\frac{dx}{x} = -\frac{dt}{\tau}$$

Then integrate both sides and don't forget to change the variables to a dummy variable and put in the limits as Brian does in his 3rd equation in the problem.

$$\begin{aligned}
 \int_{x_0}^x \frac{1}{x'} dx' &= \int_{t_0}^t -\frac{1}{\tau} dt' \\
 \ln(x')|_{x_0}^x &= -\frac{t'}{\tau}|_{t_0}^t \\
 \ln(x) - \ln(x_0) &= -(t - t_0)/\tau \\
 \ln(x/x_0) &= -(t - t_0)/\tau \text{ (remember this natural log relation, this form is more common)} \\
 x/x_0 &= e^{-\frac{t-t_0}{\tau}} \text{ (exponentiate both sides)} \\
 x(t) &= x_0 e^{-\frac{t-t_0}{\tau}}
 \end{aligned}$$

This is an important functional form where the distance is exponentially decreasing and "time constant" is  $\tau$ . The units in equation (1) are  $[m]/[s] = [m]/[s]$  so they work out. In the final solution the units in the exponential are  $[s]/[s]$  because the time constant has dimensions of seconds. Then outside of the exponential the units are  $[m] = [m]$ . It is important to remember unit analysis when solving physics problems because it can really help you figure out if your solution makes sense and also can lead you to where you went wrong. It also helps you develop a better understanding of what your solutions actually means and gives you a better physical intuition beyond the mathematics.

- b. The problem asks what happens if there is a plus sign instead of a minus sign in equation 1. The only thing that would change is that it would be a positively increasing exponential:

$$\begin{aligned}
 \frac{dx}{dt} &= \frac{x}{\tau} \\
 x(t_0) &= x_0 \\
 \int_{x_0}^x \frac{1}{x'} dx' &= \int_{t_0}^t \frac{1}{\tau} dt' \\
 \ln(x')|_{x_0}^x &= \frac{t'}{\tau}|_{t_0}^t \\
 \ln(x) - \ln(x_0) &= (t - t_0)/\tau \\
 \ln(x/x_0) &= (t - t_0)/\tau \\
 x/x_0 &= e^{\frac{t-t_0}{\tau}} \\
 x(t) &= x_0 e^{\frac{t-t_0}{\tau}}
 \end{aligned}$$

For large arbitrary  $x$  this function would not make physical sense because  $t - t_0$  would blow up. This time it takes to go a distance should not just keep increasing because eventually it will reach the limit of how fast something can travel (speed of light).

- c.) Solve a more complicated, but frequently encountered equation in physics.

$$\begin{aligned}
\frac{dx}{dt} &= x_0 \omega \sqrt{1 - \frac{x^2}{x_0^2}} \\
\frac{dx}{\sqrt{1 - \frac{x^2}{x_0^2}}} &= x_0 \omega dt \text{ (group x and t terms)} \\
\int_{x_0}^x \frac{1}{\sqrt{1 - \frac{(x')^2}{x_0^2}}} dx' &= \int_{t_0}^t x_0 \omega dt' = x_0 \omega (t - t_0)
\end{aligned}$$

Lets evaluate the left hand intergral separately. This will invole a trigonometric substitution which is a method of integration learned in calculus II.

$$\begin{aligned}
x'/x_0 &= \sin(\theta) \\
dx' &= x_0 \cos(\theta) d\theta \\
\theta &= \sin^{-1}(x'/x_0) \\
\int_{x_0}^x \frac{1}{\sqrt{1 - \frac{(x')^2}{x_0^2}}} dx' &= \int_{x_0}^x \frac{x_0 \cos(\theta)}{\sqrt{1 - \sin^2(\theta)}} d\theta \text{ (plug in the new trig substitution)} \\
&= \int_{x_0}^x \frac{x_0 \cos(\theta)}{\sqrt{\cos^2(\theta)}} d\theta \text{ (}\sin^2(\theta) + \cos^2(\theta) = 1\text{)} \\
&= \int_{x_0}^x \frac{x_0 \cos(\theta)}{\cos(\theta)} d\theta \text{ (perform the square root)} \\
&= \int_{x_0}^x x_0 d\theta \text{ (cosines cancel out)} \\
&= x_0 \theta|_{x_0}^x \text{ (perform the integration of } \theta\text{)} \\
&= x_0 \arcsin(x'/x_0)|_{x_0}^x \text{ (plug back in for } x'/x_0\text{)} \\
&= x_0(\arcsin(x/x_0) - \arcsin(x_0/x_0)) \\
&= x_0(\arcsin(x/x_0) - \arcsin(1)) \\
&= x_0(\arcsin(x/x_0) - \pi/2) \text{ (}\arcsin(1) = \pi/2\text{)}
\end{aligned}$$

Now put this back into the original equation and solve for x(t):

$$\begin{aligned}
x_0(\arcsin(x/x_0) - \pi/2) &= x_0 \omega (t - t_0) \\
(x/x_0) - \pi/2 &= \omega (t - t_0) \\
\sin^{-1}(x/x_0) &= \omega (t - t_0) + \pi/2 \\
x/x_0 &= \sin(\omega (t - t_0) + \pi/2) \\
x(t) &= x_0 \sin(\omega (t - t_0) + \pi/2)
\end{aligned}$$

The role of  $\omega$  is the frequency of oscillation of the sine function and  $x_0$  is the amplitude(maximum) of the oscillation. This is simple harmonic motion which is a common form of motion in physics

**Problem 4.** Drag forces on a falling body

Keep in mind that this is a falling body so the sign on the drag force is positive because it is acting upward on the object. If this was an ascending object the drag force would be negative because it would act down on the object.

The dimensions of  $b$  are:

$$\begin{aligned} [L/T^2] &= [L^2/T^2]b \\ b &= [1/L] \end{aligned}$$

a.) The "terminal" velocity is the maximum velocity that the object will reach while it is falling. This means the point at which the object is no longer accelerating ( $a=0$ ).

$$\begin{aligned} 0 &= -g + bv^2 \\ bv^2 &= g \\ v_t &= \sqrt{g/b} \end{aligned}$$

b.) The next step is to evaluate the time dependence of the velocity for an object starting at rest. This means that  $v(t_0) = 0$ .

$$\begin{aligned} \frac{dv}{dt} &= -g + bv^2 \\ \frac{dv}{-g + bv^2} &= dt \text{ (cast the equation in the form given in the problem)} \\ \int_0^v \frac{1}{-g + b(v')^2} dv' &= \int_{t_0}^t dt' = t - t_0 \end{aligned}$$

Then evaluate the integral on the left separately using the method of partial fractions. Here we have to manipulate the denominator by factoring it out so that it can then be written in fractions of 2 functions. The constant A and B are unknown and will be found by solving for them in terms of the original fraction.

$$\begin{aligned}
\int_0^v \frac{1}{-g + b(v')^2} dv' &= b^{-1} \int_0^v \frac{1}{-g/b + (v')^2} dv' \\
\frac{1}{(v')^2 - g/b} &= \frac{1}{(v' - \sqrt{g/b})(v' + \sqrt{g/b})} = \frac{A}{v' - \sqrt{g/b}} + \frac{B}{v' + \sqrt{g/b}} \\
1 &= A(v' + \sqrt{g/b}) + B(v' - \sqrt{g/b}) \text{ (multiply left denominator and cancel terms)} \\
Av' + Bv' &= 0 \\
A\sqrt{g/b} - B\sqrt{g/b} &= 1 \text{ (group terms with v and with constants separately)} \\
A &= -B \\
A &= \sqrt{b/g} + B \text{ (solve for A in terms of B in both equations)} \\
-B &= \sqrt{b/g} + B \text{ (plug in for A)} \\
2B &= \sqrt{b/g} \text{ (solve for B)} \\
B &= (1/2)\sqrt{b/g} \\
A &= -(1/2)\sqrt{b/g} \\
\frac{1}{(v')^2 - g/b} &= -\frac{(1/2)\sqrt{b/g}}{v' - \sqrt{g/b}} + \frac{(1/2)\sqrt{b/g}}{v' + \sqrt{g/b}} \text{ (plug back into the fraction)} \\
b^{-1} \int_0^v \frac{1}{-g/b + (v')^2} dv' &= b^{-1} \left( - \int_0^v \frac{(1/2)\sqrt{b/g}}{v' - \sqrt{g/b}} dv' + \int_0^v \frac{(1/2)\sqrt{b/g}}{v' + \sqrt{g/b}} dv' \right)
\end{aligned}$$

Solve each integral separately.

$$\begin{aligned}
\int_0^v \frac{(1/2)\sqrt{b/g}}{v' - \sqrt{g/b}} dv' &= \\
u &= v' - \sqrt{g/b}, du = dv' \text{ (u-substitution)} \\
&= \int_0^v \frac{(1/2)\sqrt{b/g}}{u} du \text{ (plug into integral)} \\
&= (1/2)\sqrt{b/g} \ln(u)|_0^v \\
&= (1/2)\sqrt{b/g} \ln(v' - \sqrt{g/b})|_0^v \text{ (plug u back in)} \\
&= (1/2)\sqrt{b/g} \ln\left(\frac{v - \sqrt{g/b}}{-\sqrt{g/b}}\right) \text{ (remember ln trick)} \\
\int_0^v \frac{(1/2)\sqrt{b/g}}{v' + \sqrt{g/b}} dv' &= \\
u &= v' + \sqrt{g/b}, du = dv' \\
&= \int_0^v \frac{(1/2)\sqrt{b/g}}{u} du \\
&= (1/2)\sqrt{b/g} \ln(u)|_0^v \\
&= (1/2)\sqrt{b/g} \ln(v' + \sqrt{g/b})|_0^v \\
&= (1/2)\sqrt{b/g} \ln\left(\frac{v + \sqrt{g/b}}{\sqrt{g/b}}\right)
\end{aligned}$$

Combine together and also notice that  $v_t = \sqrt{g/b}$  from part a.

$$\begin{aligned}
&= (1/2bv_t)(-\ln(\frac{v-v_t}{-v_t}) + \ln(\frac{v+v_t}{v_t})) \\
&= (1/2v_t)\ln(\frac{(v+v_t)(-v_t)}{(v-v_t)(v_t)}) \\
&= (1/2v_t)\ln(\frac{(v+v_t)(-1)}{(v-v_t)}) = t - t_0 \quad (t_0 = 0) \\
\ln(\frac{v+v_t}{v_t-v}) &= 2v_tbt \\
\tau &= 1/(v_tb) \quad (\tau[T] = 1/[L/T * L]) \\
\ln(\frac{v_t-v}{v+v_t}) &= -2t/\tau \quad (\text{took out a negative sign from ln which switches the fraction}) \\
\frac{v_t-v}{v+v_t} &= e^{-\frac{2t}{\tau}} \\
v_t-v &= (v+v_t)e^{-\frac{2t}{\tau}} \\
v(-e^{-\frac{2t}{\tau}}-1) &= v_t(e^{-\frac{2t}{\tau}}-1) \\
v(t) &= v_t \frac{e^{-\frac{2t}{\tau}}-1}{-e^{-\frac{2t}{\tau}}-1} \\
v(t) &= -v_t \frac{1-e^{-\frac{2t}{\tau}}}{1+e^{-\frac{2t}{\tau}}} \\
\tau &= \frac{1}{bv_t} = \frac{1}{b\sqrt{g/b}} = \frac{1}{\sqrt{gb}}
\end{aligned}$$

d.) Next we need to simplify the result using hyperbolic trigonometric functions. We are looking for  $\tanh(x)$ . I found the following representation online:

$$\tanh(x) = \frac{e^x - e^{-x}}{e^x + e^{-x}}$$

To get  $v$  in the form we have to multiply the top and the bottom by  $e^{t/\tau}$ . This is a common trick used in physics to manipulate equations into a more recognizable form.

$$\begin{aligned}
v(t) &= -v_t \frac{e^{t/\tau} \frac{1-e^{-\frac{2t}{\tau}}}{e^{t/\tau} \frac{1+e^{-\frac{2t}{\tau}}}{e^{t/\tau} + e^{-t/\tau}}}}{e^{t/\tau} + e^{-t/\tau}} \\
v(t) &= -v_t \frac{e^{t/\tau} - e^{-t/\tau}}{e^{t/\tau} + e^{-t/\tau}} \\
v(t) &= -v_t \tanh(t/\tau)
\end{aligned}$$

e.) To look at these limits let's use the exponential form of  $v(t)$ . Remember that as  $t$  approaches infinity,  $e^{-t}$  approaches 0 and as  $t$  approaches 0,  $e^{-t}$  approaches 1. Also, as  $t$  approaches infinity,  $e^t$  approaches infinity and as  $t$  approaches 0,  $e^t$  approaches 1.

Now at  $t = 0$  evaluate the limits on the velocity equation given above to get:

$$v(t) = -v_t \frac{1-1}{1+1} = 0$$

For  $t = \infty$  evaluate the limits at infinity from above to get:

$$v(t) = -v_t \frac{\infty - 0}{\infty + 0} = -v_t \frac{\infty}{\infty} = -v_t$$

There are both the results we expected. We started from rest so we would expect the velocity to be 0 at time 0. Then the terminal velocity is the final velocity met after acceleration has ceased so we would expect that at infinite time the velocity would be at the terminal velocity. Checking limits that you know is a really valuable tool for making sure the equation you obtained makes physical sense.

Now find the fraction of the velocity to the terminal velocity at a time equal to different multiples and fractions of the time constant.

$$\begin{aligned}
 t &= \tau \\
 v/v_t &= -\tanh(\tau/\tau) = -\tanh(1) = 0.76 \\
 t &= \tau/2 \\
 v/v_t &= -\tanh(1/2) = 0.46 \\
 t &= 2\tau \\
 v/v_t &= -\tanh(2) = 0.96
 \end{aligned}$$

f.) Using some graphing software plot the velocity's dependence on time. If you are not familiar with some sort of graphing program (like excel, Mathematica, Matlab, etc) see a TA or Brian early on to get help getting started on one because you will want to graph things often in this course to visualize it better.

The graph is in Fig.???. You can see that the  $v_t$  effects the amplitude of the velocity and the  $\tau$  effects how quickly the velocity changes with time. THus the  $\tau$  is more important in determining the time dependence of velocity.

FIGURE 1. The x-axis is multiples of  $\tau$  and the y axis is multiples of  $v_t$

**Problem 5.** Drag forces and horizontal motion

a.) This problem asks you to do the same thing as in problem 4 but to look at the horizontal component of the velocity. Here the important thing to remember is that the constant acceleration ( $g$ ) doesn't act on the object in the horizontal direction. Also, the drag force on an object moving horizontally has to act against the motion so it will be a negative force. Therefore, the equation looks like this:

$$\frac{dv}{dt} = -bv^2$$

Then solve the same as before:

$$\begin{aligned}\frac{dv}{v^2} &= -bdt \\ \int_v^{v_0} (v')^{-2} dv' &= -b \int_0^t dt' = -b(t-0) \\ -(v')^{-1} \Big|_v^{v_0} &= -bt \\ (1/v - 1/v_0) &= bt \\ 1/v &= bt + 1/v_0 \\ v &= \frac{1}{bt + 1/v_0} \\ v_x(t) &= \frac{v_0}{v_0 bt + 1}\end{aligned}$$

This is a good point to check limits on the equation to see if it makes sense. First, we know that at time 0 the velocity should be the initial velocity and if you plug that in you can see that is indeed true. Second, as  $t$  approaches infinity the velocity should approach 0 and by taking the limit you see that is true also. Therefore, our solution makes physical sense.

Find the time where  $v$  reaches half its initial value, which is when  $v_x/v_0 = 1/2$ :

$$\begin{aligned}v_x/v_0 = 1/2 &= \frac{1}{v_0 bt + 1} \\ (1/2)(v_0 bt + 1) &= 1 \\ (1/2)v_0 bt &= 1/2 \\ t &= \frac{1}{v_0 b}\end{aligned}$$

$1/b$  has units of distance so it sets the characteristic distance for the problem. It is the distance over which the velocity decreases in the sense that how big or small  $1/b$  is determines how fast the velocity decreases and the distance over which that decrease happens. This can be seen explicitly in the time it takes for the velocity to reach half its value. This time is proportional to  $1/b$  meaning that the bigger  $1/b$  is the longer it takes to reach half its velocity. Thus,  $1/b$  sets the distance scale.

b.) Now we need to calculate the fractional decrease of the baseball's velocity  $v/v_0$ , but first we need to figure out a way to deduce the time for the given distance. Brian speaks of an ideal time which is from the ideal relationship of distance, velocity, and time without drag.

$$\begin{aligned}d &= v_0 t \\ t_{ideal} &= d/v_0 = 16m/45m/s = 0.36s\end{aligned}$$

Then plug this into the velocity equation from part a, but remember to make it the fractional velocity by dividing both sides by the initial velocity:

$$\begin{aligned} v_x(t)/v_0 &= \frac{1}{v_0 b t_{ideal} + 1} \\ v_x(t)/v_0 &= \frac{1}{(45 \text{ m/s})(2 \times 10^{-3} \text{ m}^{-1})(0.36) s + 1} = \frac{1}{1.03} \\ v_x(t)/v_0 &= 0.97 \end{aligned}$$

c.) Now we need to integrate the velocity equation from part a to get the horizontal position as a function of time. First turn  $v_x(t) = \frac{dx}{dt}$  and group terms of x and t:

$$\begin{aligned} v_x(t) &= \frac{dx}{dt} = \frac{v_0}{v_0 b t + 1} \\ dx &= \frac{v_0 dt}{v_0 b t + 1} \\ \int_0^x dx' &= \int_0^t \frac{v_0}{v_0 b t' + 1} dt' \\ u &= v_0 b t' + 1 \\ du &= v_0 b dt', dt' = \frac{1}{v_0 b} du \\ x &= \int_0^t \frac{v_0}{v_0 b u} du \\ x &= (1/b) \ln(u)|_0^t \\ x &= (1/b) \ln(v_0 b t' + 1)|_0^t \\ x &= (1/b) \ln\left(\frac{v_0 b t + 1}{0 + 1}\right) = (1/b) \ln(v_0 b t + 1) \\ x(t) &= (1/b) \ln(v_0 b t + 1) \end{aligned}$$

d.) Now do a Taylor expansion on the horizontal distribution around  $t = 0$ , which will be useful for part d and e.

$$\begin{aligned} x(t) &= (1/b) \ln(v_0 b(0) + 1) + (1/1!)((1/b) \frac{v_0 b}{v_0 b(0) + 1})(t - 0) + (1/2!)((1/b) \frac{-v_0^2 b^2}{(v_0 b(0) + 1)^2})(x - 0)^2 + \dots \\ x(t) &= (1/b) \ln(1) + (1/b) v_0 b t - (1/2)(1/b) v_0^2 b^2 t^2 + \dots \\ x(t) &= v_0 t - (1/2) v_0^2 b t^2 + \dots \end{aligned}$$

Part d asks you to keep only the first non-zero term, which gives you:

$$x(t) \approx v_0 t$$

This is the same as the "ideal" solution you obtain when not using drag, which is the "zeroth" order correction.

e.) The second non-zero term is the first order correction.

$$x(t) \approx v_0 t - \frac{v_0^2 b t^2}{2}$$

f.) Calculate the ratio to get a rough estimate of the error as done in problem 1.

$$err \approx \frac{v_0^2 b t^2}{2 v_0 t} = \frac{v_0 b t}{2}$$

Now plug in the ideal time from part b.

$$err \approx \frac{(45m/s)(0.002m^{-1})(0.36s)}{2} = 0.016$$

This means the error is about 1.6 percent which is relatively small, indicating this ideal time is a good approximation.

g.) Calculate the time using the equation with the second term in the expansion from part e.

$$\begin{aligned} x(t) &\approx v_0 t - \frac{v_0^2 b t^2}{2} \\ 16m &\approx (45m/s)t - \frac{(45m/s)^2(0.002m^{-1})t^2}{2} \\ 2.025t^2 - 45t + 16 &= 0 \\ t &\approx \frac{45 \sqrt{(45)^2 - 4(2.025)(16)}}{2(2.025)} = \frac{45 \sqrt{2025 - 129.9}}{4.05} \\ t &\approx \frac{4543.5}{4.05} = 21.9, 0.37s \end{aligned}$$

Note that we solved a quadratic equation and it had 2 roots. In physics usually only one root is actually a physical solution so make sure when solving quadratic equations to figure out which root makes physical sense and use that one. Here the 0.37 s is the physical solution since it is close to the ideal time and the other time is way off (not physical).

$$t_{1st} \approx 0.37s$$

Now evaluate the fraction change of this time and the ideal time:

$$\frac{t_{1st} - t_{ideal}}{t_{ideal}} = 0.023$$

They differ by 2.3 percent.

h.) Now the problem asks you to calculate the actual time using the horizontal position equation from part c.

$$\begin{aligned} x(t) &= (1/b) \ln(v_0 b t + 1) \\ 16m &= \frac{1}{0.002m^{-1}} \ln((45m/s)(0.002m^{-1})t + 1) \\ 0.032 &= \ln(0.09s^{-1}t + 1) \\ 0.09s^{-1}t + 1 &= e^{0.032} \\ 0.09s^{-1}t &= 1.033 - 1 \\ t &= 0.033/0.09 = 0.367s \end{aligned}$$

This is very close to the ideal time and the first order correction to the time obtained in the previous parts of this problem. The fraction differences are:

$$\begin{aligned}\frac{t_{actual} - t_{ideal}}{t_{actual}} &= 0.019 \\ \frac{t_{actual} - t_{1st}}{t_{actual}} &= 0.0081\end{aligned}$$

They are both small indicating that this ideal and 1st order approximation of the time is a good way to get the time. The 1st order is a better approximation though. This is something to keep in mind when you have more complicated equations where you can't analytically solve for the values that you want. In these cases you will want to use approximations like this to get to a solution and it is good to know how accurate these approximations are before you use them blindly.
